## Introduction: the Ponzano-Regge state-sum model

The Ponzano-Regge state-sum model is formally defined by

$$\mathcal{Z}_{\text{PR}}(\Delta_2^*) = \sum_{\{j_f\}} \prod_f (2j_f + 1) \prod_v \{6j\}$$

where  $\Delta_2^*$  is the dual 2-skeleton of a triangulated 3-manifold  $\Delta$ .

[Ponzano, Regge (68)]

This expression is almost always **divergent**. Understanding the structure of these divergences is crucial for

- ▶ Spinfoam models, of which the PR model is the epitome.
- ▶ Group field theory, where they might generate a renormalization flow.
- ▶ Quantum topology, in order to define a *Ponzano-Regge invariant*.

## Counting the vertices of the triangulation?

Ponzano and Regge associated these divergences to the **vertices** of the simplicial complex  $\Delta$ , and proposed the improved definition

$$Z'_{\text{PR}}(\Delta_2^*) = \lim_{\Lambda \rightarrow \infty} \frac{1}{\Lambda^{3|\Delta_0|}} \sum_{\{j_f\}} \prod_f (2j_f + 1) \prod_v \{6j\}.$$

[Ponzano, Regge (68)]

Unfortunately, this fails.

[Barrett, Naish-Guzman (09)]

## Flat connections and discrete Bianchi identity

The Ponzano-Regge model can be given a gauge-theoretic definition, as the partition function of a system of **flat connections**.

$$\mathcal{Z}_{\text{PR}}(\Delta_2^*) = \int_{\text{SU}(2)^E} dA \prod_f \delta(H_f(A))$$

- ▶ Discrete connection:  $A = (g_e)_e \in \text{SU}(2)^E$
- ▶ Haar measure:  $dA = \prod_e dg_e$

In this setting,

- ▶ Curvature of  $A$ :

$$H(A) = (H_f(A))_f = \prod_{e \in \partial f} g_e^{\pm 1} \in \text{SU}(2)^F$$

- ▶ Gauge transformation of  $A$  along  $k \in \text{SU}(2)$  (assume **single vertex**):

$$\gamma_A(h) = (kg_e k^{-1})_e.$$

## Freidel and Louapre's proposal

Some of these  $\delta$  functions are redundant, as there are **discrete Bianchi identities**: for each vertex  $v \in \Delta_0$ , there is an ordering of the faces surrounding it such that

$$\prod_f^{\rightarrow} H_f^{\pm 1} = 1.$$

Freidel and Louapre then proposed to collapse a spanning tree in  $\Delta$  to remove these redundancies. This amounts to removing a **tree of faces** in  $\Delta_2^*$ , yielding

$$Z'_{FL}(\Delta_2^*) = \int_{\text{SU}(2)^E} dA \prod_{f \in \Delta_2^* \setminus T} \delta(H_f(A))$$

[Freidel, Louapre (03)]

## Counter-examples

For lens spaces, there are triangulations such that  $\Delta_2^*$  has only one face, and

$$Z'_{FL}(\Delta_2^*) = \int_{\text{SU}(2)} dg \delta(g^P) = \infty.$$

The same happens for the 3-torus.

*“In general we do not expect this invariant to be finite for topologically non trivial closed manifold.”*

[Freidel, Louapre (03)]

## Counting the bubbles of the foam?

It was proposed that these are higher analogues of loop divergences, arising because of the **spins** get **unbounded** along **bubbles**: collections of faces forming closed surfaces.

[Perez, Rovelli (00)]

In 3 dimensions, there is correspondance between vertices of  $\Delta$  and bubbles of  $\Delta_2^*$ . This correspondance breaks down in four dimensions. The notion of **bubble divergence** is the **more general** one.

This idea was recently used to estimate the divergence degree for certain foams, coined 'type 1':

$$\mathcal{Z}_{\text{PR}}(\text{type 1}) = \left( \sum_{j=0}^{\wedge} (2j + 1)^2 \right)^{B-1} .$$

[Freidel, Gurau, Oriti (09)]

## Our goal: divergence degree and dominant part

We consider the regularized expression

$$\mathcal{Z}_\tau(\Gamma, G) = \int_{\text{SU}(2)^E} dA \prod_f K_\tau(H_f(A))$$

with

- ▶  $\Gamma$  an arbitrary **cell 2-complex** (manifold or not) with **one vertex**
- ▶  $G$  a **compact** (semi-simple) **Lie group**
- ▶  $K_\tau$  the **heat kernel** on  $G$ ,  $K_\tau(g) \underset{\tau \rightarrow 0}{\sim} \underbrace{\left( \frac{1}{\sqrt{4\pi\tau}} \right)^{\dim G}}_{\Lambda_\tau} \exp\left(-\frac{|g|^2}{4\tau}\right)$

[Freidel, Louapre (03)]

and look for an asymptotic estimate of the form

$$\mathcal{Z}_\tau(\Gamma, G) \underset{\tau \rightarrow 0}{\sim} \Lambda_\tau^{\Omega(\Gamma, G)} \underbrace{\mathcal{Z}'(\Gamma, G)}_{< \infty}$$

## An implicit assumption

In previous investigations, it was always implicitly assumed that the divergences can be captured by a **purely combinatorial** criterion:

- ▶ vertices in  $\Delta$  (Ponzano-Regge, Freidel-Louapre, Barrett-Naish-Guzman)
- ▶ bubbles in  $\Delta_2^*$  (Perez-Rovelli, Freidel-Gurau-Oriti)

This implies that  $\Omega$  is a multiple of  $\dim G$ .

**This is not true in general.**

This is why the Ponzano-Regge, or Freidel-Louapre, regularizations fail, and why the Freidel-Gurau-Oriti estimate cannot be general.

## Our results

- ▶ The combinatorial powercounting is true in trivial cases
  - ▶  $\Gamma$  simply connected
  - ▶  $G$  Abelian

where indeed

$$\Omega(\Gamma, G) = (\dim G) b_2(\Gamma).$$

- ▶ In more general cases, this formula is **twisted**, and  $\Omega$  is not a multiple of  $\dim G$ :

$$\Omega(\Gamma, G) = \tilde{b}_2.$$

- ▶ (The dominant part  $\mathcal{Z}'(\Gamma, G)$  can be related to Reidemeister torsion, work in progress.)

# Outline

From vertices to bubbles

Evaluating the divergence degree

Generalized Laplace approximation

Example: lens spaces

Cohomological interpretation

The case of manifolds

## Generalized Laplace approximation

The integral

$$\mathcal{Z}_\tau(\Gamma, G) = \int_{\mathrm{SU}(2)^E} dA \prod_f K_\tau(H_f(A)) \underset{\tau \rightarrow 0}{\sim} \Lambda_\tau^{(\dim G)F} \int_{\mathrm{SU}(2)^E} dA e^{-\frac{\sum_f |H_f(A)|^2}{4\tau}}$$

is peaked on the set  $\mathcal{F}$  of **flat connections**  $\phi$ , for which  $H(\phi) = 1$ . In the neighborhood of  $\mathcal{F}$ , we have  $A = \exp_\phi(a)$  for  $a \in N_\phi \mathcal{F}$ , and

$$\sum_f |H_f(A)|^2 = \|dH_\phi(a)\|_{\mathfrak{g}^F}^2.$$

Gaussian integrals transversally to  $\mathcal{F}$ .

## A caveat: singular connections.

However, because  $1 \in G^F$  is usually **not a regular value** of the smooth map  $H$ , i.e.  $H$  is not submersive on  $\mathcal{F}$ ,  $\mathcal{F}$  is **not a manifold**, but rather an 'algebraic set'.

The **singularities** of  $\mathcal{F}$  are the connections  $\phi$  such that

$$\ker dH_\phi \neq T_\phi \mathcal{F}.$$

We **assume** they **do not contribute to the integral**.

- ▶ True in two dimensions. [Sengupta (03)]
- ▶ We know one counter-example, see our paper.

The **non-singular** flat connections do form a **manifold**. Since

$$\dim \ker dH_\phi \geq \dim T_\phi \mathcal{F},$$

they are the flat connections where  $H$  has **maximal rank**.

## Powercounting

The Gaussian integrals bring about **convergent factors**, one per transverse direction:

$$\int_{N_\phi \mathcal{F}} da e^{-\|dH_\phi(a)\|_{g^F}^2 / 4\tau} = \Lambda_\tau^{-\dim N_\phi \mathcal{F}} \underbrace{\det \left( (dH_\phi^\perp)^\dagger dH_\phi^\perp \right)^{-1/2}}_{\text{Gaussian determinant, indep. of } \tau}$$

Hence

$$\mathcal{Z}_\tau(\Gamma, G) = \Lambda_\tau^{\Omega(\Gamma, G)} \int_{\mathcal{F}} d\phi f(\phi),$$

with

$$\Omega(\Gamma, G) = (\dim G)F - \dim N_\phi \mathcal{F}$$

i.e.

$$\Omega(\Gamma, G) = (\dim G)F - \max_{\mathcal{F}} \text{rk } H.$$

## Cohomological interpretation

Our result can be given a **cohomological interpretation**. This is a neat way to **disentangle**, about a flat connection  $\phi$ , the variations  $a \in T_\phi G^E$  which

- ▶ **leave  $\phi$  flat** ( $a \in \ker dH_\phi$ )
  - ▶ because they are infinitesimal gauge transformations ( $a \in \text{Im } d\gamma_\phi$ )
  - ▶ not for this reason ( $a \notin \text{Im } d\gamma_\phi$ )
- ▶ **introduce curvature** ( $a \notin \ker dH_\phi$ )

$$\underbrace{C_\phi^0 = \mathfrak{g}}_{\text{inf. gauge transfo.}} \xrightarrow{d\gamma_\phi} \underbrace{C_\phi^1 = T_\phi G^E}_{\text{variations about } \phi} \xrightarrow{dH_\phi} \underbrace{C_\phi^2 = \mathfrak{g}^F}_{\text{inf. holonomies}}$$

[Witten (89), Barrett-Naish-Guzman (09)]

$\Omega(\Gamma, G) = b_\phi^2$  is the **second Betti number** in this **twisted cohomology**.

Note: when  $\phi = 1$ , this is nothing but the **cellular cohomology** of  $\Gamma$  with **coefficients in  $\mathfrak{g}$** , and then

$$\Omega(\Gamma, G) = (\dim G)b^2(\Gamma).$$

# Outline

From vertices to bubbles

Evaluating the divergence degree

The case of manifolds

Three dimensions

Four dimensions

Conclusions

## Triangulation dependence of the divergence degree

Assume now that  $\Gamma$  is the dual 2-skeleton of a triangulation  $\Delta^{(d)}$  of a  $d$ -manifold  $M^{(d)}$ .

Elementary manipulations on the expression of  $\Omega(\Gamma, G)$  yield

$$\Omega(\Delta^{(d)}, G) = \underbrace{\dim \mathcal{M} - \dim \zeta + (\dim G)}_{\text{topological invariant}} \chi(M^{(d)}) + \underbrace{(\dim G) \sum_{j=0}^{d-3} (-1)^{d+j} |\Delta_j^{(d)}|}_{\text{triangulation dependent}}.$$

with

- ▶  $\mathcal{M}$  is the **moduli space of flat connections**
- ▶  $\zeta$  is the isotropy group of non-singular flat connections
- ▶  $|\Delta_j^{(d)}|$  the number of  $j$ -simplices

## Three dimensions

In **three dimensions**, this becomes

$$\Omega(\Delta^{(d)}, G) = \dim \mathcal{M} - \dim \zeta \\ + (\dim G) |\Delta_0^{(3)}|.$$

Back to Ponzano and Regge's original intuition ("divergences are associated to vertices of the triangulation"):

- ▶ They missed the topological term, and this is why their regularization failed.
- ▶ But! They were right about the **variation of  $\Omega$**  in a Pachner move:

$$\delta_{\text{Pachner}} \left( \Omega(\Delta^{(d)}, G) \right) = (\dim G) \delta_{\text{Pachner}} \left( |\Delta_0^{(3)}| \right).$$

## Four dimensions

In **four dimensions**, the formula becomes

$$\begin{aligned}\Omega(\Delta^{(d)}, G) &= \dim \mathcal{M} - \dim \zeta + (\dim G)\chi(M^{(4)}) \\ &\quad + (\dim G) \left( |\Delta_1^{(4)}| - |\Delta_0^{(4)}| \right).\end{aligned}$$

Again, the variation of  $\Omega$  in a Pachner move is correctly captured by the combinatorial estimate, the number of bubbles being

edges - vertices.

## Conclusions

- ▶ The divergence degree of a foam is given by the number of transverse directions to the set of flat connections.
- ▶ The notion that it counts the “number of bubbles” is correct, but in a subtle sense:  $\Omega$  is the second Betti number in a **twisted cohomology**. In particular it is **not a multiple of  $\dim G$** .
- ▶ In the case of manifolds, the old arguments relying on Pachner moves capture the **variation of  $\Omega$** , but **not  $\Omega$  itself**.

Can these methods be used to study the gravitational models? We do not know.

Thanks!
